Euthymic Patients with Bipolar Disorder Show Decreased Reward Learning in a Probabilistic Reward Task

Diego A. Pizzagalli, Elena Goetz, Michael Ostacher, Dan V. Iosifescu, and Roy H. Perlis

Background: Bipolar disorder (BPD) features cycling mood states ranging from depression to mania with intermittent phases of euthymia. Bipolar disorder subjects often show excessive goal-directed and pleasure-seeking behavior during manic episodes and reduced hedonic capacity during depressive episodes, indicating that BPD might involve altered reward processing. Our goal was to test the hypothesis that BPD is characterized by impairments in adjusting behavior as a function of prior reinforcement history, particularly in the presence of residual anhedonic symptoms.

Methods: Eighteen medicated BPD subjects and 25 demographically matched comparison subjects performed a probabilistic reward task. To identify putative dysfunctions in reward processing irrespective of mood state, primary analyses focused on euthymic BPD subjects (n = 13). With signal-detection methodologies, response bias toward a more frequently rewarded stimulus was used to objectively assess the participants’ propensity to modulate behavior as a function of reinforcement history.

Results: Relative to comparison subjects, euthymic BPD subjects showed a reduced and delayed acquisition of response bias toward the more frequently rewarded stimulus, which was partially due to increased sensitivity to single rewards of the disadvantageous stimulus. Analyses considering the entire BPD sample revealed that reduced reward learning correlated with self-reported anhedonic symptoms, even after adjusting for residual manic and anxious symptoms and general distress.

Conclusions: The present study provides preliminary evidence indicating that BPD, even during euthymic states, is characterized by dysfunctional reward learning in situations requiring integration of reinforcement information over time and thus offers initial insights about the potential source of dysfunctional reward processing in this disorder.

Key Words: Anhedonia, bipolar disorder, dopamine, reinforcement learning, reward, depression
Methods and Materials

Participants

Bipolar disorder participants were recruited from patients followed for long-term treatment at the Bipolar Clinic and Research Program at Massachusetts General Hospital (MGH) and were initially evaluated with the Affective Disorder Evaluation (ADE; 19), which includes modified mood and psychosis modules from the Structured Clinical Interview for DSM-IV Axis I Disorders (SCID) (20). The BPD patients were enrolled if the following inclusion criteria were met: 1) current diagnosis of bipolar I or bipolar II disorder on the basis of the ADE; 19); 2) absence of any other current primary Axis I or II diagnosis, including substance abuse or dependence within the past 12 months; 3) absence of electroconvulsive therapy in the past 6 months; and 4) absence of past history of major depressive episodes (MDE) with psychotic features (MDE) with psychotic features. Patients with recent substance abuse or dependence were excluded to avoid potential confounds deriving from possible dopaminergic abnormalities associated with this disorder (21,22). Additionally, the SCID mood module was administered on the day of the study session to confirm diagnosis.

A total of 25 BPD patients were enrolled, but 7 were excluded owing to task non-compliance (n = 2), performance at chance level (n = 4), or misunderstanding of task instructions (n = 1). On the basis of clinician ratings that occurred on the day of the study session, subjects with a score on the Young Mania Rating Scale (23) (YMRS) ≥ 12 were defined as being in a hypomanic state, whereas those with a score on the 17-item Hamilton Rating Scale for Depression (24) (HRSD) > 8 were defined as being in a depressed state. The BPD participants who met neither of these conservative thresholds were classified as currently euthymic (all euthymic participants had a YMRS score ≤ 6). On the basis of these criteria, the BPD sample (n = 18) included 13 euthymic, 2 currently depressed, and 3 currently hypomanic participants. Of the 18 BPD participants, 6 had a history of substance dependence and 1 had past substance abuse. Thirteen of the 18 patients met criteria for bipolar I disorder (11 of 13 of the euthymic BPD patients), whereas the remaining patients met criteria for bipolar II disorder. As in prior studies (6,8–14), all patients were taking psychotropic medications at the time of testing (Table 1). All ratings were performed by psychiatrists certified and monitored for reliability as part of the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) study (19,25,26). Inter-rater reliability for the HRSD (κ = .82), YMRS (κ = .79), and SCID-based BPD diagnosis (κ > .80) was satisfactory among the authors’ team.

The BPD patients were compared with 25 healthy comparison participants recruited through community advertisements. Comparison subjects were enrolled if they had no medical or neurological illness, no current or past Axis I diagnoses (SCID, Neurological Illness, No Current or Past Axis I Diagnoses (SCID, AD), and General Distress–Anxious Symptoms, GDA; General Distress–Depressive Symptoms, GDD), and has shown satisfactory validity and reliability (28,29). The task is a reward-based paradigm in which correct identifications of two ambiguous stimuli are differentially rewarded. This paradigm has been found to reliably produce a response bias in control participants, such that as the task proceeds, the more frequently rewarded stimulus is preferentially selected (15–17,30). This pattern is consistent with the so-called “matching law” (31), which postulates that response selection relies on reinforcement history.

In brief, participants are instructed to identify whether a long or short mouth is presented within a schematic face by pressing one of two buttons on the keyboard (“z” or “/”, counterbalanced). The face first appears without a mouth, and then either a long (13 mm) or short mouth (11.5 mm) is presented for 100 msec. Stimulus exposure and sizes were chosen on the basis of prior studies (15) and after pilot testing to optimize the psychometric properties of the task (e.g., overall accuracy rates of 75%–85%).

Participants are instructed that for some of their correct responses, they will be rewarded and see a message “Correct!! You won 5 Cents.” The task consists of three blocks of 100 trials each. These are referred to as block 1 (trials 1–100), block 2 (trials 101–200), and block 3 (trials 201–300). The two stimuli are presented with equal frequency. Importantly, correct identification of one stimulus (“rich stimulus”) is rewarded three times more often than the other (“lean stimulus”). The reward feedback is presented only 40 times, 30 times for the rich and 10 times for the lean stimulus. At the outset, participants are instructed that the goal of the task is to win as much money as possible and that they would earn between $3 and $7 on the basis of their performance. They are explicitly informed that not all correct responses will receive a reward feedback. They are not informed, however, that one of the stimuli would be rewarded more frequently.

Data Reduction

Task performance was assessed by computing response bias, discriminability, and reaction times. Hit rates (number of hits/(number of hits + number of misses)) and miss rates (1 – hit rates) were also computed but were considered secondary variables because they are imperfect measures of performance when response biases are present (32). Response bias and discriminability were computed with the following formulae (33):

![Table 1. Summary of Psychotropic Medications in BPD Patients](https://www.sobp.org/journal)
Response Bias:

\[ \log \hat{b} = \frac{1}{2} \log \left( \frac{\text{Rich}_{\text{correct}} \times \text{Lean}_{\text{incorrect}}}{\text{Rich}_{\text{incorrect}} \times \text{Lean}_{\text{correct}}} \right) \]

Discriminability:

\[ \log \hat{d} = \frac{1}{2} \log \left( \frac{\text{Rich}_{\text{correct}} \times \text{Lean}_{\text{correct}}}{\text{Rich}_{\text{correct}} \times \text{Lean}_{\text{incorrect}}} \right) \]

A high response bias emerges if a subject shows a high number of correct identifications (i.e., high hit rate) for the rich stimulus and a low number of correct identifications (i.e., high miss rate) for the lean stimulus. Accordingly, response bias indexes an individual’s preference toward the more frequently rewarded (rich) stimulus. Because reinforcers are stimuli that increase the likelihood of a given behavioral response (34), response bias toward the rich stimulus can be used to measure the extent to which behavior is modulated by reinforcement history. Discriminability, conversely, is a measure of the subjects’ ability to perceptually distinguish between the two stimulus types and thus serves as an assessment of task difficulty.

To test the hypothesis that reduced reward learning would be associated with anhedonic symptoms, an “anhedonic” BDI-II subscore was computed by summing the following BDI-II items (15,35): loss of pleasure (item #4), loss of interest (item #12), loss of energy (item #15), and loss of interest in sex (item #21).

**Statistics**

To test whether BPD was characterized by abnormal reward processing irrespective of current mood state, the main statistical analyses focused on the euthymic BPD subjects (n = 13). The χ² tests and unpaired t tests were performed to test for possible group differences in sociodemographic variables. To evaluate mood symptoms, a mixed analysis of variance (ANOVA) was run on MASQ scores, with Group (comparison subjects, euthymic BPD subjects) and MASQ subscales (GDA, AA, GDD, AD) as factors.

For the reward task, separate mixed ANOVAs with Group and Block (1,2,3) as factors were run on response bias and discriminability scores separately. For reaction times and hit rate scores, Stimulus Type (Rich, Lean) was added as a repeated measure.

When required, the Greenhouse-Geisser correction was used. Significant findings were followed up by post hoc Newman-Keuls. Pearson correlations and hierarchical regression analyses between response bias and measures of depressive and manic symptoms (HRSD, BDI-II, MASQ scales) were run within the entire BPD sample (n = 18). Throughout the analyses, two-tailed tests were used. Effect sizes are reported in the form of partial η² and Cohen d values.

**Results**

**Demographics, Symptom Severity, and Mood Variables**

Comparison (n = 25) and euthymic BPD (n = 13) subjects did not differ significantly with respect to demographic variables (Table 2) (also, no differences emerged when considering the entire BPD sample, n = 18). For the euthymic BPD patients, the mean HRSD and YMRS scores were 3.38 (SD = 2.57) and 1.9 (SD = 2.33), respectively. Relative to comparison subjects, euthymic BPD patients had significantly higher BDI-II scores [8.38 ± 6.70 vs. 3.40 ± 3.59, t(36) = 3.00, p < .005]; the BPD subjects’ mean BDI-II score was, however, below the threshold for mild depression (BDI ≥ 14).

The ANOVA on the MASQ scores revealed main effects of MASQ subscale [F(3,108) = 188.01, p < .001, η² = .44] and Group [F(1,36) = 15.53, p < .005, partial η² = .30] but no interaction (p > .35). Post hoc Newman-Keuls tests indicated that group differences were driven by significantly higher anhedonic depression scores in euthymic than comparison subjects (p < .005), whereas the two groups did not differ in the other MASQ sub-scales (all p values > .28; Table 2).

**Probabilistic Reward Task**

**Response Bias.** The ANOVA revealed a significant effect of Block [F(2,72) = 6.57, p < .002, partial η² = .15], which was due to significantly higher response bias in Blocks 2 and 3 compared with Block 1 (Newman-Keuls p values < .005). The main effect of Group [F(1,36) = 6.28, p < .020, partial η² = .15] and the Group X Block interaction [F(2,72) = 3.30, p < .043, partial η² = .08] were also significant. As shown in Figure 1, euthymic BPD patients had significantly lower overall

response bias than comparison subjects (.22 ± .18 vs. .07 ± .16; Cohen d = −.87). Post hoc Newman-Keuls further revealed significantly higher response biases in Blocks 2 and 3 compared with Block 1 for euthymic BPD patients (p values < .005). For comparison subjects, no changes in response bias occurred across the blocks (p values > .40). Relative to comparison subjects, euthymic BPD patients had significantly lower response bias in Block 1 only (p < .0004; Cohen d = −.93). A main effect of Group remained when considering the entire BPD sample [n = 18] irrespective of current clinical state or when considering only euthymic BPD subjects with BP I [n = 11] [F values > 4.22, p values < .046].

Moreover, exploratory analyses evaluating the potential effects of different classes of medication on response bias (e.g., drug blocking dopaminergic effects) revealed no significant effects [see Supplement 1 for more detail].

To further explore the timing of response bias acquisition, a one-way ANOVA that considered the first half (trials 1–50) and second half (trials 51–100) of Block 1, Block 2 (trials 101–200), and Block 3 (trials 201–300) was performed for comparison and BPD subjects separately. For both groups, the main effect of Block was significant [both F values > 3.02, both p values < .035]. Within-group post hoc analyses revealed that comparison subjects had significantly higher response bias in the second half of Block 1, Block 2, and Block 3 compared with the first half of Block 1 (all p values < .05). For BPD patients, however, no differences emerged between the early and late phases of Block 1; instead, they showed significantly higher response biases in Blocks 2 and 3 compared with the first half of Block 1 (both p values < .036).

To exclude the possibility that group differences in response bias were due to elevated depressive symptoms in BPD patients, a set of hierarchical regression analyses was performed (see refs. [36,37] for a rationale of a regression analysis approach when covariates and independent variables are correlated). To this end, the total BDI-II scores were entered in the first step of the regression followed by Group (dummy coded) to predict response bias in Block 1, 2, and 3 as well as response bias across the 300 trials. Findings revealed that Group was a significant predictor of response bias in Block 1 (ΔR² = .20), Block 2 (ΔR² = .11) and over the entire 300 trials (ΔR² = .16) after removing variance associated with BDI-II scores [all ΔF(1,35) > 4.24, all p values < .048]. Similar findings emerged when considering anhedonic BDI-II scores: Group was a unique predictor of response bias in Block 1 (p < .01), Block 2 (p = .085), and over the 300 trials (p < .035).

**Discriminability.** No significant effects emerged [all F values < 2.22, all p values > .14].

**Reaction Time.** No effects involving Group emerged [all F values < 1.46, all p values > .23].

**Hit Rate.** The ANOVA on hit rates revealed a significant main effect of Condition [F(1,36) = 30.85, p < .001, partial η² = .46; rich stimulus > lean stimulus] and a significant Block × Condition interaction [F(2,72) = 7.69, p < .001, partial η² = .18]. As in a prior study using this paradigm (15), the Block × Condition interaction was due to significant hit rate differences between the stimuli, which increased across the blocks.

Critically, this effect was qualified by a significant Group × Condition × Block interaction [F(2,72) = 3.22, p = .046, partial η² = .08] (Figures 2A and 2B). To evaluate this triple interaction, follow-up Group × Block ANOVAs were performed for the rich and lean hit rates separately. For the rich stimulus, the main effect of Group was reliable [F(1,36) = 8.13, p = .007, partial η² = .18], owing to significantly higher hit rates (or conversely, significantly lower miss rate) for the comparison than euthymic BPD subjects (.89 ± .07 vs. .82 ± .05; Cohen d = 1.04; Figure 2C). Notably, comparison and BPD subjects had virtually identical lean accuracy scores (.75 ± .14 vs. .75 ± .11), and neither the Group [F(1,36) = .003, p > .95] nor the Group × Block [F(2,72) = 2.03, p > .13] interaction were significant.

**Probability Analyses.** The previous analyses indicate that euthymic BPD patients had significantly lower response bias and significantly higher miss rate for the more frequently rewarded (rich) stimulus. To investigate these findings in more detail, we computed the probability of missing a rich stimulus as a function of the outcome in the immediately preceding trial. To this end, we first identified all trials in which a correct identification of the rich or lean stimulus was rewarded and then computed the probability of a rich miss in the subsequent trial. Analogous computations were performed for trials immediately after a correct identification of the rich or lean stimulus that was not rewarded (because a reward was not scheduled). Note that these analyses allowed us to test the strength of the response bias toward the rich stimulus as a function of: a) which stimulus had been rewarded in the preceding trial, and b) proximity of reward delivery. After an arcsine transformation was applied (38), these probability values were entered in a Group × Stimulus Type (rich vs. lean) × Preceding Trial (rewarded vs. not rewarded) ANOVA. For the sake of simplicity, only effects involving Group are reported, and untransformed values are shown.

The ANOVA revealed a significant main effect of Group [F(1,36) = 7.19, p < .011, partial η² = .167] and a trend for the 3-way interaction [F(1,36) = 2.84, p = .10, partial η² = .073]. Post hoc tests indicated that group differences were driven by significantly higher probability of a rich miss in euthymic BPD patients than comparison subjects in two of the four experimental conditions: when a rich trial was preceded by a) a non-rewarded rich stimulus (p < .019; Cohen d = .74), or b) a rewarded lean stimulus (p < .004; Cohen d = .80) (Figure 3). Moreover, within-group analyses indicated that euthymic BPD patients but not comparison subjects had significantly higher probability of rich misses immediately after a non-rewarded rich stimulus than a non-rewarded lean stimulus (p < .028 vs. p > .19, respectively).

**Relationships with Clinical Symptoms.** Within the entire BPD sample (n = 18), overall reward learning [ΔResponse Hit Rate]
Bias = Response Bias(Block 3) – Response Bias(Block 1) was negatively correlated with total HRSD ($r = -0.51, p < 0.030$), total BDI ($r = -0.57, p < 0.015$), and anhedonic BDI-II ($r = -0.51, p < 0.030$) scores but not with the YMRS score ($r = -0.18, p > 0.45$) or MASQ Ad score ($r = -0.22, p > 0.35$). A hierarchical regression analysis indicated that the anhedonic BDI-II sub-score (entered in the third step) was a significant predictor of $\Delta$Response Bias [standardized $\beta$ coefficients = $-0.609, t = -3.04, p < .010$], even after removing variance associated with the total YMRS score (entered in the first step) and the two MASQ anxiety scores (entered concurrently in the second step) [$\Delta R^2 = .35, \Delta F(1,13) = 9.22, p < .010$]. Accordingly, patients reporting relatively elevated anhedonic symptoms were characterized by decreased reward learning even when controlling for their residual manic and anxious symptoms or general distress (Figure 4).

**Figure 2.** Mean accuracy for the rich and lean stimulus across the three blocks (panels A and B) and averaged across the three blocks (panel C) for healthy comparison ($n = 25$) and euthymic bipolar disorder (BPD) ($n = 13$) subjects. In (C), arrows denote significant post hoc tests; error bars represent standard errors.

**Discussion**

The goal of the this study was to test the hypotheses that: a) BPD patients are characterized by abnormal reward processing even during a euthymic state, and b) the presence of residual anhedonic symptoms would exacerbate this dysfunction. With a probabilistic reward task, which assesses how behavior is modulated by reinforcement history, we found that both euthymic and symptomatic BPD patients showed reduced and delayed acquisition of response bias toward the more frequently rewarded stimulus, even after controlling for residual depressive or anhedonic symptoms. In addition, BPD patients reporting anhedonic symptoms in their daily life (e.g., loss of pleasure) showed the most impaired reward learning. Highlighting the specificity of this finding, a relationship between anhedonic symptoms and reduced response bias remained after controlling for subjects’ residual manic and anxious symptoms as well as general distress, replicating recent findings from two non-clinical samples (15,17) and a medication-free sample with major depressive disorder (Pizzagalli, Iosifescu, Hallet, Ratner, Fava, unpublished). Unlike

**Figure 3.** Probability of miss rates for healthy comparison ($n = 25$) and euthymic bipolar disorder (BPD) ($n = 13$) subjects as a function of whether the preceding rich or lean trial was rewarded or not. Arrows denote significant post hoc tests; error bars represent standard errors.

**Figure 4.** Pearson correlation ($r = -0.59, p < .010$) for the entire bipolar disorder (BPD) sample ($n = 18$) between $\Delta$Response Bias and the residualized Beck Depression Inventory (BDI)-II anhedonic subscore, which was computed by removing variance associated with the total Young Mania Rating Scale score and the two Mood and Anxiety Symptom Questionnaire anxiety scores (MASQ Aroused [AA] and MASQ General Distress-Anxious Symptoms [GDA]).
our recent findings in major depression, BPD patients exhibited cumulative learning over the course of the three blocks; however, the blunted nature of the response bias and its delayed acquisition point to a dysfunctional integration of reward information in early phases of the experiment.

Of note, additional analyses indicated that reduced response bias in BPD patients was not due to general task deficits, as evident from the lack of group differences in discriminability or reaction time. Rather, the performance of BPD participants was characterized by their increased tendency to misclassify the more frequently rewarded (rich) stimulus, whereas they showed no differences from comparison subjects in classifying the lean stimulus. Interestingly, elevated miss rates for the rich stimulus emerged only when it was immediately preceded by either a non-rewarded rich stimulus or by a rewarded lean stimulus, indicating that BPD subjects were impaired in developing a response bias toward the more frequently rewarded stimulus in the absence of a proximal rich reward or after receiving a reward for the less advantageous response.

The finding of increased misclassification of the rich stimulus immediately after a rewarded lean stimulus is intriguing, particularly in light of theoretical accounts linking BPD to dysregulation of the behavioral approach system (BAS; 39–41), a system assumed to regulate appetitive motivation and goal-directed behavior in response to signals of reward (42). Notably, in BPD, increased BAS sensitivity and experiences of goal-striving and -attainment events predicted future manic symptoms (43–46), and behavioral activation scores distinguished euthymic BPD patients from healthy control subjects (46). The current finding that reduced response bias toward the more frequently rewarded stimulus was partially explained by increased sensitivity and behavioral switching after rewards of the less advantageous (lean) stimulus is consistent with the general hypothesis of heightened responsivity to minimal environmental incentives in BPD (39–41,46). Our results also extend a recent report of maladaptive BAS hypersensitivity in subjects with bipolar spectrum disorder (47). In the current study, an increased sensitivity to the infrequently occurring lean reward might, in turn, have led to impaired cumulative reward learning in BPD subjects.

Overall, the present findings of impaired integration of reward feedback are in line with recent reports showing that medicated euthymic and acutely manic BPD patients displayed an increased tendency to select the less favorable of two possible response options in a gambling task (14) and exhibited deficits in learning fluctuating stimulus-reward contingencies (12,13). Moreover, because omission of reward could be interpreted by the participants as reflecting a potential erroneous response, the increased miss rate observed in trials immediately after a non-rewarded rich trial is consistent with a prior finding of increased behavioral switches after error feedback in mania (14). Unlike prior studies, however, the current findings provide direct evidence that BPD, even during euthymic states, is characterized by reduced and delayed integration of reinforcements over time and thus provide novel insights about the potential source of dysfunctional reward processing in this disorder. (Note that the BPD subjects achieved a comparable response bias by the third block of the task, indicating that they were able to integrate reinforcement information, albeit in a delayed way. The control group, by contrast, achieved their maximum response bias very early in the course of the task [by the second half of block 1], and their failure to show increasing biases over time might be due to ceiling effects.)

The limitations of the present study should be acknowledged. First, the sample of BPD, particularly euthymic, patients was relatively small, and all patients were medicated. We note that all prior studies investigating reward processing in BPD have also assessed medicated subjects (6,8–14), highlighting the practical and ethical difficulties of investigating medication-free BPD subjects. Second, no patient was in a manic state, and the range of clinical symptomatology was limited. Thus, it is unclear whether acutely manic BPD patients might show potentiated rather than blunted reward learning. Third, patients with a history of substance abuse or dependence within the past year were excluded to avoid potential confounds deriving from possible dopaminergic abnormalities that characterize these disorders (21,22). Thus, it is unclear whether our findings will generalize to other BPD samples. Fourth, only reward feedbacks were included, so future studies will be needed to evaluate whether BPD patients might show deficits in other types of incentive learning (e.g., punishment feedback).

In sum, BPD patients, particularly those with residual anhedonic symptoms, showed reduced behavioral bias toward a more frequently rewarded stimulus. Future studies will be required to evaluate whether this abnormality is associated with dysfunction in brain regions coding the representation of reward values (e.g., orbitofrontal cortex; 48,49) and/or the downregulation of dopaminergic synaptic mechanisms, which have been hypothesized to follow the hyperdopaminergic state observed in mania (4).

Supplementary data

Title: Euthymic Patients with Bipolar Disorder Show Decreased Reward Learning in a Probabilistic Reward Task

Authors: Diego A. Pizzagalli, Elena Goetz, Michael Ostacher, Dan V. Iosifescu, and Roy H. Perlis

Medication Effects. Five BPD subjects were receiving lithium, 5 valproate, 11 anticonvulsants, 8 antipsychotics, and 9 antidepressants at the time of testing (see Table 1, Main Text). To assess for potential medication effects on response bias, exploratory Medication Status (e.g., participants with vs. without lithium) x Block ANOVAs were performed for each class of medication. Both when considering the entire BPD sample and the euthymic BPD patients separately, no significant effects involving Medication Status emerged (all Fs < 1.92, all ps > 0.18).

In addition, to assess for potential effects of dopaminergic-acting medications on response bias, a Medication Status x Block ANOVA was performed to compare BPD subjects receiving drugs with blocking/inhibiting dopaminergic effects (n = 7) vs. those receiving drugs with either no direct or some agonistic dopaminergic effects (n = 10). One subject who was receiving a medication in both categories was excluded from the analysis (see Supplementary Table 1 where relevant medications for all subjects are reported). No significant effects involving Medication Status emerged (all Fs < 1.68, all ps > 0.20).

In light of the limited sample size, findings from these analyses testing for potential effects should be considered preliminary and are only presented for descriptive purposes.
Supplementary Table 1: Summary of drugs with some antagonistic/agonistic dopaminergic effects.

Seven subjects received at least one drug with blocking/inhibiting dopaminergic effects, whereas four subjects were prescribed at least one drug with some agonistic dopaminergic effects. Six subjects received medications with no direct dopaminergic effects (e.g., Valproic Acid, Lamotrigine). In the statistical analyses, subjects receiving drugs with either no direct or some agonistic dopaminergic effects were combined (n = 10).
